Early Human Speciation, Brain Expansion and Dispersal Influenced by African Climate Pulses

Susanne Shultz1, Mark Maslin2*

Abstract

Early human evolution is characterised by pulsed speciation and dispersal events that cannot be explained fully by global or regional paleoclimate records. We propose that the collated record of ephemeral East African Rift System (EARS) lakes could be a proxy for the regional paleoclimate conditions experienced by early hominins. Here we show that the presence of these lakes is associated with low levels of dust deposition in both West African and Mediterranean records, but is not associated with long-term global cooling and aridification of East Africa. Hominin expansion and diversification seem to be associated with climate pulses characterized by the precession-forced appearance and disappearance of deep EARS lakes. The most profound period for hominin evolution occurs at about 1.9 Ma; with the highest recorded diversity of hominin species, the appearance of Homo (sensu stricto) and major dispersal events out of East Africa into Eurasia. During this period, ephemeral deep-freshwater lakes appeared along the whole length of the EARS, fundamentally changing the local environment. The relationship between the local environment and hominin brain expansion is less clear. The major step-wise expansion in brain size around 1.9 Ma when Homo appeared was coeval with the occurrence of ephemeral deep lakes. Subsequent incremental increases in brain size are associated with dry periods with few if any lakes. Plio-Pleistocene East African climate pulses as evinced by the paleo-lake records seem, therefore, fundamental to hominin speciation, encephalisation and migration.

Introduction

Human evolution is characterised by speciation, extinction and dispersal events that cannot currently be explained by global or regional paleoclimate records [1–3]. Despite the widespread distribution of hominins across Africa and Eurasia after two million years ago, the majority of hominins species originated in East Africa and subsequently colonised the rest of Africa and Eurasia [4–5]. Arguably the most important episode in hominin evolution occurred in this region during the period bracketing 1.8–1.9 Ma when hominin diversity reached its highest level with the appearance of the Homo (sensu stricto) and new species of the Paranthropus genera. In addition to speciation, a second major process that begins during this period is the episodic migration of hominins out of the Rift Valley and into Eurasia. This period also witnessed the most dramatic increases in hominin brain size; early representatives of the Homo erectus sensu lato (Homo erectus and H. ergaster) in Africa had a brain that was >80% larger than the gracile australopithecine Australopithecus afarensis and ~40% larger than Homo (Australopithecus) habilis (Figure 1). However, there remains no consensus for what conditions or mechanisms drove these major changes.

Environmental pressures have long been assumed to play a key role in hominin speciation and adaptation [6]. The savannah hypothesis implicates the long-term trend towards increased aridity and the expansion of the savannah as a major driver of hominin evolution [7–8]. As opposed to long-term directional trends, the variability selection hypothesis advocates the role of environmental unpredictability in selecting for behavioural or ecological flexibility [9–12]. However, these hypotheses, which emphasise long-term trends toward either a drier or more variable climate, do not explain the pulsed nature of hominin speciation and migration events. Two alternative hypotheses, however, can account for the discrete and episodic nature of hominin evolutionary events. The turnover pulse hypothesis, developed to explain discrete patterns in ungulate speciation, suggests that acute climate shifts drive adaptation and speciation [13]. However, the evidence for this hypothesis is equivocal as the stacked benthic foraminifera δ18O record, which is thought to represent global climate, may [14] or may not [1] contain temporal signatures associated with key events in hominin evolution. A more recent hotly debated hypothesis, is the pulsed climate variability hypothesis, that highlights the role of extreme wet-dry climate cycles specific to East Africa in driving hominin evolution [15].

This last hypothesis is based on the distinct geologic and climate conditions of East Africa. The East African Rift System (EARS), one of the most extensive geological features on the Earth’s surface, runs north-south for around 4500 km from Syria through East Africa to Mozambique [16–17]. The formation of the EARS had a profound effect on the long-term climate of East Africa. Evidence from carbon isotope records from both soil carbonates [18–20] and biomarkers (n-alkanes) extracted from deep-sea sediments [21] provide clear evidence of a progressive vegetation
shift from C3 (~trees and shrubs) to C4 (~tropical grasses) plants during the Plio-Pleistocene. This shift has been ascribed to increased aridity due to the orographic barrier produced by the progressive rifting of East Africa during this period [22].

The progressive formation of the EARS also led to the production of isolated basins within which lakes could form. Southward propagation of rifting and magmatic activity resulted in the formation of lake basins first in the northern parts of the EARS. For example, fluviolacustrine history of the Afar, Omo-Turkana and Baringo-Bogoria Basins in the north began in the Middle and Late Miocene, whereas the oldest lacustrine sequences in the central and southern segments of the rift in Kenya and Tanzania are found in the Early Pliocene [23]. Despite the southward progression of tectonic processes in East Africa, ephemeral deep-water lakes seem to occur in separate basins at approximately the same time suggesting a climatic control [17,24]. Figure 1 shows a compilation of all the current known occurrences of both ephemeral deep freshwater and shallow alkaline lakes in the EARS for the last 5 Myrs. There is growing evidence that during each of these major lake phases the large fresh-water lakes appeared and disappeared on a precessional time-scale [24–27], which may reflect repeated periods of extremely wet and arid conditions and significant vegetation shifts within the EARS [28]. Up to and including 2.6 Ma, these lake phases track 400 ka eccentricity cycles. Subsequently, these lake phases still occur at the peak eccentricity forcing but only at ~1.8 Ma and ~1.0 Ma. The most significant lake phase at 1.9–1.7 Ma [1], that corresponds with the intensification of the Walker circulation [29–31]. At this time the E-W sea surface temperature gradients in both the Pacific and Indian Oceans increased [29,31] intensifying the E-W moisture transport in the tropics, which greatly increased rainfall variability both on a precession and an ENSO (El Niño Southern Oscillation) time-scales.

Figure 1. Top panel shows the East African Rift valley lake variability shown both as the number of Basin containing deep or shallow lakes and the calculated normalised lake index. The putative hominin dispersals ‘D’ (red arrows out of Africa, dotted within Africa only) are shown above. Middle panel shows African hominin species diversity over time. Bottom panel shows hominin brain estimates for Africa and Eurasia. Hominin specimen dates and brain size estimates were taken from Shultz et al [3]. East African hominin diversity at each 100 kyrs interval were estimated using first (FAD) and last appearance dates (FAD) from the literature [2,35–36,46]. *Homo erectus* and *H. ergaster* were treated as a ‘super-species’ referred to in the Figure key and text as *Homo erectus (sensu lato)*, but distinct regional processes in brain size change were identified by separating the specimens by continent in the analyses. Hominin migration dates were estimated by FAD of hominin specimens outside of EARS.

Lake variability index was calculated by collating the published geological evidence for the appearance of either deep ephemeral or shallow alkaline lakes in seven major Basins [15,17,23–27,34–37]. The index was normalised by dividing by 7 to produce a range from 0 to 1.

Materials and Methods

Data
Regional aeolian terrigenous dust records from off the coast of West Africa (ODP 659), Arabian Sea (ODP 721/722) and Mediterranean (ODP 967) and global stacked benthic foraminifera δ18O paleoclimate records were collated from published sources (see File S1). Data on hominin species first and last appearance dates (FAD and LAD), postulated timing of dispersal events and brain size were collated from the literature (see Tables S1 and S2 in File S1). Absolute hominin brain capacity was used with no correction for body size for two reasons. First there is significant controversy over body size estimates and second recent work shows that absolute brain size is the best predictor for cognitive ability [32–33]. We used the FAD and LAD to generate estimates of hominin diversity during each 100 kyrs block between the present and 3 Ma. We then derived a species turnover vector by differenting richness estimates from adjacent time periods. The lake variability index was calculated by collating the published geological evidence for the appearance of either deep ephemeral or shallow alkaline lakes in seven major Basins in 50 kyrs sections over the last 5 Myrs [15,17,23–27,34–37]. These Basins are; Olduvai (Tanzania), Magadi-Natron-Olorgesailie (N. Tanzania and S. Kenya), Central Kenya Rift (Kenya), Baringo-Bogoria (Kenya), Omo-Turkana-Suguta (N. Kenya), Ethiopian Rift (South and Central Ethiopia) and Afar (N. Ethiopia). The index was normalised by dividing by 7 to produce a range from 0 to 1.

Statistics
To identify best fit models relating paleoclimate to both the lake index and hominin evolution, we used a the stepAIC function in R package MASS to select the best fit model [30], see Figure 2. For comparison of fit, we then ran these models through a linear model to extract p values and r² (see File S1).

Results and Discussion
To establish whether EARS lake formation is associated with paleoclimate trends, we used regional (aeolian terrigenous dust records from off the coast of West Africa ODP 659, Arabian Sea ODP 721/722 and Mediterranean ODP 967) and global (stacked benthic foraminifera δ18O) paleoclimate records to predict the occurrence of EARS lakes (see File S1). The best-fit model requires both the regional and global records to explain what is occurring within the Rift valley as evinced by the collated lake record (Table 1). As it has been suggested that the lakes represent pulsed changes in local climate conditions, we also incorporated measures of climate pulses or shifts in regional dust records [2] (Table 1). These measures of climate turnover substantially improve model fit, indicating that the occurrence of widespread ephemeral deep lakes is a pulsed system influenced both by regional and global changes. Hence over the Plio-Pleistocene, East African climate is best characterised as a long-term trend towards increasing aridity punctuated by periods of precession-forced high rainfall leading to the periodic appearance of deep freshwater lakes. It is these pulses of increased productivity and shifts in habitat availability that may explain hominin speciation and dispersal events.

As the lakes appear to be a proxy for local climate pulses, we use the lake index to explicitly test the pulsed climate variability hypothesis [15] by evaluating the relationship between paleoclimate and hominin evolution. Our approach is a significant advance on previous models, as we incorporate the lake index as a proxy for local climate, together with regional and global paleoclimate records. By incorporating multiple records, we can identify which aspects of paleoclimate best predict hominin evolution. Over the

Figure 2. Relative impact on model fit of different paleoclimate indicators as predictors of aspects of African hominin evolution (species turnover, brain size change, dispersal events, and overall diversity). Values represent the deltaAIC change [38] from dropping each of the indicators from the global model. ODP721 was not incuded in the migration analyses due to a high VIF. Non-climate variables included in these models are not shown here as they vary across analyses but can be found in File S1.
doi:10.1371/journal.pone.0076750.g002
past 3 Myrs, East African hominin species diversity and dispersal events are predicted by both lake presence and Mediterranean dust deposition (Table 2 and Figure S1 in File S1). Of these two predictors, the lake index has the strongest impact on model fit for both the dispersal and diversity models. In the period following 2 Ma, the fossil record suggests there are periodic hominin dispersal events out of East Africa [39]. Around 1.8 Ma, there is evidence of Homo georgicus and H. ertecus in Eurasia and H. habilis in southern Africa suggesting they may have migrated out of East Africa before this time. This first pulse is followed by later dispersals into both Eurasia and southern Africa by H. heidelbergensis and finally anatomically modern H. sapiens. Previous explanations for the onset of dispersal have been tied to hominins acquiring the necessary competencies in foraging or locomotion, life history [40], material technology or cognition to expand their range. However, the small-brain and body sizes and technologically crude early Dmanisi hominins may suggest that it was not a cognitive, a technological or a locomotory threshold, which facilitated early dispersal [41]. Additionally, once hominins overcame the constraining factors, one would assume that there would be continual, if low-level dispersal. In contrast, the fossil record suggests that dispersal events were discrete events. The regional differentiation between African and Asian H. ertecus populations, and the eventual transition of the former into H. heidelbergensis, and between H. sapiens and H. neanderthalensis suggests that there was limited gene flow between Africa and Asia. A parsimonious explanation for periodic migration events is that they were forced or facilitated by climatic conditions. We suggest that both the lake presence and absence could be associated with dispersal events. For example when the lake Basins are dry they become ‘hyper arid’ and thus inhabitable and hence hominin population would have been forced to migrate to the north and south [34] but there would also have been a server lack of resources. Thus dispersal is more likely to have occurred when the Basins were completely filled with water, as there would have been limited space for the hominin populations on the tree covered Rift shoulders and river flood plains [34]. The wet conditions would however been more conducive to dispersal as hominin populations would have expanded due to the availability of water and food and could have followed the Nile tributaries northward [42]. So the

occurrence of deep freshwater lakes would have forced expanding hominin populations both northwards and southwards generate a pumping effect pushing them out of East Africa towards the Ethiopian highlands and the Sinai Peninsula or into Southern Africa with each successive precessional cycle.

A final characteristic that defines hominin evolution is increasing brain size over the Pleistocene. Figure 1 shows a new compilation of estimated cranial capacity [3], with each specimen plotted against its date. Hominin encephalisation is a combination of processes: an underlying gradual trend towards larger brains is punctuated by several large step increases at ~100 ka and ~1.9 Ma [3]. Global benthic foraminifera δ18O and Indian Ocean aeolian records do not explain these processes [3]. Here we use a comprehensive set of paleoclimate indicators: East African Rift lake presence, regional Aeolian flux records from the Arabian Sea, the Mediterranean and the East Atlantic together global benthic foraminifera δ18O with to develop models predicting

Full model results are presented in the supplementary information. Best fit model was identified using the stepAIC function in R package Mass [38]. AIC change represents the impact on model fit by dropping each predictor (positive change indicates that dropping a factor worsens model fit). Variables listed in decreasing order of influence on model fit. The first model covers the period from 0–3 Ma and the second from 350 ka – 2.6 Ma, due to the reduced coverage of the AFLP records.

The migration model is one of three scenarios (see Table S2 in File S1). As species richness is temporally autocorrelated, we also ran a model of species turnover (net change in richness for each time period). All global and regional paleoclimate databases were included in the model. As above, StepAIC was used to identify best-fit models. No r2 is reported for migration as we assumed a binomial error structure. Full model results are available in File S1.

doi:10.1371/journal.pone.0076750.t002
The largest change in brain size, associated with the appearance of the *Homo erectus* super-species is associated with the period of maximal ephemeral lake coverage. This jump of 80% expansion in cranial capacity occurs during one of only two periods when there is evidence for at least 5 of the 7 major intra-rift lake basins being active. Subsequently, the underlying trend towards increasing brain size in *Homo* is most strongly correlated with both decreases in lake presence and high levels of dust deposition in the Mediterranean ODP967 record (Table 3), indicating drier conditions in East Africa [43]. Brain size change in African hominins was not predicted by either Arabian Sea dust or global benthic foraminifera δ¹⁸O records. In contrast, patterns of hominin encephalisation in Eurasia were positively associated with lake presence. This later finding stems from the association between dispersal events and lakes: larger brained African hominins colonised Eurasia during periods when extensive lakes in the EARS push them out of Africa (Figure 1). Taken together, this suggests that small steps in brain expansion in Africa may have been driven by regional aridity. In contrast, the great leap forward in early *Homo* brain size at 1.8 Ma was associated with the novel ecological conditions [28] associated with the appearance and disappearance of deep-freshwater lakes long the whole length of the EARS (Figure 1). The effects of the lake variability may have been enhanced at 1.8 Ma as key geological features that fragment the current lake Basins had yet to form; including the Barrier volcano separating Lake Turkana and the Suguta valley (~1.4 Ma eastern side and ~0.7 Ma western side) and the Emurungangogol volcano (~1.3 Ma), and Namaranu volcano (0.8 Ma) which separate Lake Baringo and the Suguta Valley [35–37,44]. Hence during wet periods at about 1.8 Ma one huge lake may have extended periodically from the Omo National Park in the north to just north of Lake Baringo in the south covering over 16,000 km².

The appearance of the *Homo erectus sensu lato* in Africa represents a fundamental turning point in hominin evolution. Not only was there a dramatic increase in brain size, but also in life history (shortened inter-birth intervals, delayed development), body size, shoulder morphology allowing throwing of projectiles [45], ecological flexibility [46] and social behaviour [47]. Some of these changes are consistent with a change in strategy towards flexibility and the ability to colonise novel environments. In contrast, the robust *Australopithecus* sp. adopted specialised habitat and dietary strategies [8]. Thus, two strategies arose during this

All available paleoclimate databases were incorporated in the global models. Age was incorporated in the models to minimise the probability of spurious, non-causal temporal correlation between encephalisation and long-term paleoclimate trends. StepAIC was used to identify model with most support. Full model results are available in File S1.

doi:10.1371/journal.pone.0076750.t003
Conclusion

That the presence of Rift lakes is concurrent with major events in hominin evolution suggests that we must embrace a new perspective on how environmental conditions drove human evolution. Paleoclimate derived from stacked benthic foraminifera δ18O or aeolian dust records has been unable explain the occurrence of discrete evolutionary phases in the hominin fossil record [2–3,15], the incorporation of the Rift lakes as both a climate indicator and landscape feature provides this missing environmental evidence. The unusual geology and climate of the East African Rift System introduced selective environmental pulses, which not only drove speciation but also subsequent dispersal events. However, our study suggests that this is not a simple relationship between climate variability and hominin evolution. As significant hominin brain expansion occurred at ~1.8 Ma coeval with occurrence of massive ephemeral deep-water lakes, while subsequent expansions are associated with extreme dry periods. Hence, though the Pulse Climate Variability hypothesis is an interesting starting point for discussing early human evolution it may to simplistic to capture the whole range of evolutionary forcing occurring in East Africa in the Plio-Pleistocene. We may have to consider that climate was not always the underlying cause and that intrinsic social factors and intra-species competition may have play a significant role [50]. However, understanding the role of East African lakes does seem to be required to explain why and when hominin species arose and eventually left East Africa.
